Understanding Label Bias in Single Positive Multi-Label Learning

Anonymous authors

Paper under double-blind review

ABSTRACT

Annotating data for multi-label classification is prohibitively expensive because every category of interest must be confirmed to be either present or absent. Recent work on single positive multi-label (SPML) learning has shown that it is possible to train effective multi-label classifiers using only one positive label per image. The standard benchmarks for SPML are derived from traditional multi-label classification datasets by retaining one positive label for each training example (chosen uniformly at random) and discarding all other labels. However, in realistic annotation settings it is not likely that positive labels are chosen uniformly at random. In this work, we explore the effect of label bias in SPML.

1 Introduction

Multi-label classification aims to predict the presence or absence of every category from a collection of categories of interest (Tsoumakas & Katakis, 2007). This is a generalization of the standard multi-class classification setting, in which the categories are mutually exclusive. Multi-label classification is often more realistic than multi-class classification in domains like natural image classification where multiple categories tend to co-occur (Wang et al., 2016; Wei et al., 2015).

The primary obstacle to training multi-label classifiers is the expense of exhaustively annotating the presence and absence of every category of interest. To mitigate this problem, Cole et al. (2021) introduces the setting of *single positive multi-label* (SPML) classification, which aims to train multi-label image classifiers using only one positive label per image. SPML algorithms have been shown to approach the performance of fully supervised multi-label classifiers using far fewer labels.

The standard benchmarks for SPML are artificially generated from fully annotated multi-label classification datasets. For each training image, one positive label is chosen uniformly at random to be retained and all other labels are discarded. While this simple model is a reasonable starting point, it is unlikely to reflect realistic annotator behavior (Spain & Perona, 2011). To apply SPML in realistic settings, we must understand how different positive label selection biases affect performance.

Our key contributions are as follows: (1) We extend the SPML benchmarks in Cole et al. (2021) by generating new label sets based on different models of annotator bias. (2) We provide the first study of the effect of label bias in SPML, filling a crucial gap in the literature with significant implications for the real-world applicability of SPML. Data and code will be publicly released upon acceptance.

2 RELATED WORK

SPML. Cole et al. (2021) formalized the SPML setting and introduced the initial benchmarks and algorithms for the problem. Subsequent work has used these benchmarks to develop new SPML algorithms (Kim et al., 2022; Abdelfattah et al., 2023; 2022; Ke et al., 2022; Zhou et al., 2022; Xu et al., 2022; Verelst et al., 2023). We complement this work by extending the benchmarks in Cole et al. (2021) and clarifying the role of label selection bias in SPML.

Models of annotator behavior. The benchmarks in Cole et al. (2021) are unlikely to reflect the behavior of real annotators, who are more likely to mention an object if it is larger or closer to the center of the frame (Berg et al., 2012) or may neglect to mention it if it is "too obvious" (Spain & Perona, 2011). We take inspiration from this literature for our models of annotator behavior.

3 BIAS MODELS FOR SINGLE POSITIVE MULTI-LABEL ANNOTATION

Let (\mathbf{x}, \mathbf{y}) denote a training example, where $\mathbf{x} \in \mathbb{R}^p$ is an image and $\mathbf{y} \in \{0, 1\}^L$ is a label vector. Suppose we ask an annotator to name one class in \mathbf{x} . We want to model the probability P(i) that class $i \in \{1, \ldots, L\}$ will be selected. As in Cole et al. (2021), we assume $y_i = 0 \implies P(i) = 0$.

Uniform bias. Choose one positive label uniformly at random:

$$P_{\text{uniform}}(i) = \mathbb{1}_{[y_i=1]} \times 1/|\{i \in \{1, \dots, L\} : y_i = 1\}|. \tag{1}$$

Size bias. Choose a category in proportion to the fraction of the image it occupies:

$$P_{\text{size}}(i) = \mathbb{1}_{[y_i=1]} \times A_i / \sum_{j=1}^{L} A_j$$
 (2)

where A_i is the sum of the bounding box areas of all instances of class i.

Location bias. Choose a category more often if it occurs close to the center of the image:

$$P_{\text{location}}(i) = \mathbb{1}_{[y_i=1]} \times D_i^{-1} / \sum_{j=1}^{L} D_j^{-1}$$
(3)

where D_i is the average distance from the center of all instances of class i.

Semantic bias. Determine probabilities based on empirical object spotting data:

$$P_{\text{semantic}}(i) = \mathbb{1}_{[y_i=1]} \times f_i / \sum_{j=1}^{L} f_j$$
(4)

where f_i is the empirical spotting frequency for category i, which is derived from annotator studies by the COCO team (Lin et al., 2014). See Appendix B for details.

4 RESULTS & DISCUSSION

For each bias, we generate three independent realizations of SPML labels (see Appendix A.2). For each dataset realization and loss, we use the code from Cole et al. (2021) to train and evaluate SPML methods on COCO (Lin et al., 2014). We present the results in Table 1. Additional bias implementation details in Appendix A.1.

Table 1: Test set mean average precision (MAP) results for different bias models and training losses. Values for $P_{\rm uniform}$ are copied from their respective papers.

	P_{uniform}	$P_{ m size}$	P_{location}	P_{semantic}
\mathcal{L}_{AN} (Cole et al., 2021)	62.3	56.97 ± 0.05	60.94 ± 0.16	59.84 ± 0.36
$\mathcal{L}_{\text{AN-LS}}$ (Cole et al., 2021)	64.8	56.68 ± 0.32	62.71 ± 0.12	59.80 ± 0.14
$\mathcal{L}_{\text{ROLE}}$ (Cole et al., 2021)	66.3	60.11 ± 0.12	66.38 ± 0.03	66.39 ± 0.01
\mathcal{L}_{EM} (Zhang et al., 2021)	<u>70.7</u>	61.15 ± 0.06	68.36 ± 0.04	65.56 ± 0.42

We make three observations. (i) The ranking of different methods is similar across bias types. This provides some evidence that the standard $P_{\rm uniform}$ benchmarks are a reasonable surrogate for more realistic biases that might be encountered in practice. (ii) Performance often drops significantly when we change from $P_{\rm uniform}$ to other biases. Averaging over losses, the drop is largest for $P_{\rm size}$ (-7.3 MAP) and smallest for $P_{\rm location}$ (-1.4 MAP). (iii) Different losses have different sensitivities to label bias. $\mathcal{L}_{\rm AN-LS}$ (-5.1 MAP) and $\mathcal{L}_{\rm EM}$ (-5.7 MAP) lose more performance on average than $\mathcal{L}_{\rm AN}$ (-3.1 MAP) and $\mathcal{L}_{\rm ROLE}$ (-2.0 MAP). These observations suggest that SPML algorithm rankings are roughly stable under different label biases, but the performance under $P_{\rm uniform}$ tends to overestimate the performance under other biases. These results add new dimensions to the SPML literature. We will publicly release our data and code to facilitate future investigations on label bias and SPML.

URM STATEMENT

At least one key author of this work meets the URM criteria of ICLR 2023 Tiny Papers Track.

A IMPLEMENTATION DETAILS

A.1 BIAS MODELS

In this section we provide a few details for the non-trivial bias models: $P_{\rm size}$, $P_{\rm location}$, and $P_{\rm semantic}$. The equations are reproduced here for convenience, but are identical to those in the main paper.

Size bias. We define

$$P_{\text{size}}(i) = \mathbb{1}_{[y_i=1]} \times A_i / \sum_{j=1}^{L} A_j$$

where A_i is the the sum of the bounding box areas of all instances of class i. Note that we do not make any modifications to handle intersecting bounding boxes, so $\sum_{j=1}^{L} A_j$ may be larger than the image size.

Location bias. We define

$$P_{\text{location}}(i) = \mathbb{1}_{[y_i=1]} \times D_i^{-1} / \sum_{j=1}^{L} D_j^{-1}$$

where D_i is the average distance from the center of all instances of class i. D_i is implemented as the Euclidean distance between the center of the image and the center of the object bounding box. We also add a small value $\epsilon > 0$ to each D_i to prevent division by zero for objects in the exact center of the image.

Semantic bias. We define

$$P_{\text{semantic}}(i) = \mathbb{1}_{[y_i=1]} \times f_i / \sum_{j=1}^{L} f_j$$

where f_i is the empirical spotting frequency for category i, which is derived from annotator studies by the COCO team (Lin et al., 2014). Further details can be found in Appendix B.

A.2 Label Set Generation

Like Cole et al. (2021), we generate SPML training data by sampling labels from a fully-labeled multi-label classification dataset. Given a bias model $P \in \{P_{\text{uniform}}, P_{\text{size}}, P_{\text{location}}, P_{\text{semantic}}\}$, we can fix a random seed and generate an SPML training set. For each training image, we (i) randomly choosing one positive label according to P and (ii) mark all other labels as "unknown". For this work, we generate 3 realizations for each bias model with different seeds. Once generated, these SPML training sets are static. Training labels are not re-sampled during training. The validation and test sets are fully labeled.

B COCO OBJECT SPOTTING DATA

To build $P_{\rm semantic}$, we use object spotting data collected according to the protocols in Lin et al. (2014). The data consists of annotations of the form (pixel_x, pixel_y, category_id) for images in the COCO 2014 official validation set. Note that this data was collected by the COCO authors in 2017, and is different from the original object spotting data used to prepare the COCO 2014 dataset.

We use this data to compute empirical object spotting frequencies f_i for $i \in \{1, ..., L\}$ as follows. First, we filter out any spotting instances that are not inside of a bounding box of the appropriate

category. Using the remaining data, we compute the empirical frequency of category i, which we call w_i . Given a training image, we then define

$$f_i = \mathbb{1}_{[y_i = 1]} \cdot w_i$$

which we plug in to the definition of $P_{\text{semantic}}(i)$.
